Nobel Lecture:
Inflation and Unemployment

Milton Friedman

University of Chicago

In the past several decades, professional views on the relation between inflation and unemployment have gone through two stages and are now entering a third. The first was the acceptance of a stable trade-off (a stable Phillips curve). The second was the introduction of inflation expectations, as a variable shifting the short-run Phillips curve, and of the natural rate of unemployment, as determining the location of a vertical long-run Phillips curve. The third is occasioned by the empirical phenomenon of an apparent positive relation between inflation and unemployment. The paper explores the possibility that this relation may be more than coincidental.

When the Bank of Sweden established the prize for economic science in memory of Alfred Nobel in 1968, there doubtless was—as there doubtless still remains—widespread skepticism among both scientists and the broader public about the appropriateness of treating economics as parallel to physics, chemistry, and medicine. These are regarded as "exact sciences" in which objective, cumulative, definitive knowledge is possible. Economics and its fellow social sciences are regarded more nearly as branches of philosophy than of science properly defined, enmeshed with values at the outset because they deal with human behavior. Do not the social sciences, in which scholars are analyzing the behavior

of themselves and their fellowmen, who are in turn observing and reacting to what the scholars say, require fundamentally different methods of investigation than the physical and biological sciences? Should they not be judged by different criteria?

I. Social and Natural Sciences

I have never myself accepted this view. I believe that it reflects a misunderstanding not so much of the character and possibilities of social science as of the character and possibilities of natural science. In both, there is no "certain" substantive knowledge; only tentative hypotheses that can never be "proved" but can only fail to be rejected, hypotheses in which we may have more or less confidence, depending on such features as the breadth of experience they encompass relative to their own complexity and relative to alternative hypotheses, and the number of occasions on which they have escaped possible rejection. In both social and natural sciences, the body of positive knowledge grows by the failure of a tentative hypothesis to predict phenomena that the hypothesis professes to explain; by the patching up of that hypothesis until someone suggests a new hypothesis that more elegantly or simply embodies the troublesome phenomena, and so on ad infinitum. In both, experiment is sometimes possible, sometimes not (witness meteorology). In both, no experiment is ever completely controlled, and experience often offers evidence that is the equivalent of controlled experiment. In both, there is no way to have a self-contained closed system or to avoid interaction between the observer and the observed. The Gödel theorem in mathematics, the Heisenberg uncertainty principle in physics, the self-fulfilling or self-defeating prophecy in the social sciences all exemplify these limitations.

Of course, the different sciences deal with different subject matter, have different bodies of evidence to draw on (for example, introspection is a more important source of evidence for social than for natural sciences), find different techniques of analysis most useful, and have achieved differential success in predicting the phenomena they are studying. But such differences are as great among, say, physics, biology, medicine, and meteorology as between any of them and economics.

Even the difficult problem of separating value judgments from scientific judgments is not unique to the social sciences. I well recall a dinner at a Cambridge University college when I was sitting between a fellow economist and R. A. Fisher, the great mathematical statistician and geneticist. My fellow economist told me about a student he had been tutoring on labor economics, who, in connection with an analysis of the effect of trade unions, remarked, "Well surely, Mr. X (another economist of a different political persuasion) would not agree with that." My colleague regarded this experience as a terrible indictment of economics

because it illustrated the impossibility of a value-free positive economic science. I turned to Sir Ronald and asked whether such an experience was indeed unique to social science. His answer was an impassioned no, and he proceeded to tell one story after another about how accurately he could infer views in genetics from political views.

One of my great teachers, Wesley C. Mitchell, impressed on me the basic reason why scholars have every incentive to pursue a value-free science, whatever their values and however strongly they may wish to spread and promote them. In order to recommend a course of action to achieve an objective, we must first know whether that course of action will in fact promote the objective. Positive scientific knowledge that enables us to predict the consequences of a possible course of action is clearly a prerequisite for the normative judgment whether that course of action is desirable. The Road to Hell is paved with good intentions, precisely because of the neglect of this rather obvious point.

This point is particularly important in economics. Many countries around the world are today experiencing socially destructive inflation, abnormally high unemployment, misuse of economic resources, and, in some cases, the suppression of human freedom not because evil men deliberately sought to achieve these results, nor because of differences in values among their citizens, but because of erroneous judgments about the consequences of government measures: errors that at least in principle are capable of being corrected by the progress of positive economic science.

Rather than pursue these ideas in the abstract (I have discussed the methodological issues more fully in Friedman [1953]), I shall illustrate the positive scientific character of economics by discussing a particular economic issue that has been a major concern of the economics profession throughout the postwar period, namely, the relation between inflation and unemployment. This issue is an admirable illustration because it has been a controversial political issue throughout the period, yet the drastic change that has occurred in accepted professional views was produced primarily by the scientific response to experience that contradicted a tentatively accepted hypothesis—precisely the classical process for the revision of a scientific hypothesis.

I cannot give here an exhaustive survey of the work that has been done on this issue or of the evidence that has led to the revision of the hypothesis. I shall be able only to skim the surface in the hope of conveying the flavor of that work and that evidence and of indicating the major items requiring further investigation.

Professional controversy about the relation between inflation and unemployment has been intertwined with controversy about the relative role of monetary, fiscal, and other factors in influencing aggregate demand. One issue deals with how a change in aggregate nominal demand,

however produced, works itself out through changes in employment and price levels; the other, with the factors accounting for the change in aggregate nominal demand.

The two issues are closely related. The effects of a change in aggregate nominal demand on employment and price levels may not be independent of the source of the change, and conversely the effect of monetary, fiscal, or other forces on aggregate nominal demand may depend on how employment and price levels react. A full analysis will clearly have to treat the two issues jointly. Yet there is a considerable measure of independence between them. To a first approximation, the effects on employment and price levels may depend only on the magnitude of the change in aggregate nominal demand, not on its source. On both issues, professional opinion today is very different than it was just after World War II because experience contradicted tentatively accepted hypotheses. Either issue could therefore serve to illustrate my main thesis. I have chosen to deal with only one in order to keep this lecture within reasonable bounds. I have chosen to make that one the relation between inflation and unemployment, because recent experience leaves me less satisfied with the adequacy of my earlier work on that issue than with the adequacy of my earlier work on the forces producing changes in aggregate nominal demand.

II. Stage 1: Negatively Sloping Phillips Curve

Professional analysis of the relation between inflation and unemployment has gone through two stages since the end of World War II and is now entering a third. The first stage was the acceptance of a hypothesis associated with the name of A. W. Phillips (1958) that there is a stable negative relation between the level of unemployment and the rate of change of wages—high levels of unemployment being accompanied by falling wages, low levels of unemployment by rising wages. The wage change in turn was linked to price change by allowing for the secular increase in productivity and treating the excess of price over wage cost as given by a roughly constant markup factor.

Figure 1 illustrates this hypothesis, where I have followed the standard practice of relating unemployment directly to price change, short-circuiting the intermediate step through wages.

This relation was widely interpreted as a causal relation that offered a stable trade-off to policymakers. They could choose a low unemployment target, such as U_L. In that case they would have to accept an inflation rate of A. There would remain the problem of choosing the measures (monetary, fiscal, perhaps other) that would produce the level of aggregate nominal demand required to achieve U_L, but if that were done, there need be no concern about maintaining that combination of unemployment

Rate of price change
$$\frac{1}{P}\frac{dP}{dt}$$

FIG. 1.—Simple Phillips curve

and inflation. Alternatively, the policymakers could choose a low in-flation rate or even deflation as their target. In that case they would have to reconcile themselves to higher unemployment: U_0 for zero inflation, U_H for deflation.

Economists then busied themselves with trying to extract the relation depicted in figure 1 from evidence for different countries and periods, to eliminate the effect of extraneous disturbances, to clarify the relation between wage change and price change, and so on. In addition, they explored social gains and losses from inflation on the one hand and un-employment on the other, in order to facilitate the choice of the "right" trade-off.

Unfortunately for this hypothesis, additional evidence failed to conform with it. Empirical estimates of the Phillips curve relation were un-satisfactory. More important, the inflation rate that appeared to be consistent with a specified level of unemployment did not remain fixed: in the circumstances of the post–World War II period, when governments everywhere were seeking to promote "full employment," it tended in any one country to rise over time and to vary sharply among countries. Looked at the other way, rates of inflation that had earlier been associated with low levels of unemployment were experienced along with high levels of unemployment. The phenomenon of simultaneous high inflation and high unemployment increasingly forced itself on public and professional notice, receiving the unlovely label of "stagflation."

Some of us were skeptical from the outset about the validity of a stable Phillips curve, primarily on theoretical rather than empirical grounds (Friedman 1966a, 1966b, 1968a, 1968b). What mattered for employment, we argued, was not wages in dollars or pounds or kronor but real wages—what the wages would buy in goods and services. Low unemployment would, indeed, mean pressure for a higher real wage—but real wages could be higher even if nominal wages were lower, provided that prices were still lower. Similarly, high unemployment would, indeed, mean

pressure for a lower real wage—but real wages could be lower, even if nominal wages were higher, provided prices were still higher.

There is no need to assume a stable Phillips curve in order to explain the apparent tendency for an acceleration of inflation to reduce un-employment. That can be explained by the impact of *unanticipated* changes in nominal demand on markets characterized by (implicit or explicit) long-term commitments with respect to both capital and labor. Long-term labor commitments can be explained by the cost of acquiring information by employers about employees and by employees about alternative employment opportunities plus the specific human capital that makes an employee's value to a particular employer grow over time and exceed his value to other potential employers.

Only surprises matter. If everyone anticipated that prices would rise at, say, 20 percent a year, then this anticipation would be embodied in future wage (and other) contracts, real wages would then behave pre-cisely as they would if everyone anticipated no price rise, and there would be no reason for the 20 percent rate of inflation to be associated with a different level of unemployment than a zero rate. An unanticipated change is very different, especially in the presence of long-term commit-ments—themselves partly a result of the imperfect knowledge whose effect they enhance and spread over time. Long-term commitments mean, first, that there is not instantaneous market clearing (as in markets for perishable foods) but only a lagged adjustment of both prices and quantity to changes in demand or supply (as in the house-rental market); second, that commitments entered into depend not only on current observable prices but also on the prices expected to prevail throughout the term of the commitment.

III. Stage 2: Natural Rate Hypothesis

Proceeding along these lines, we (in particular, E. S. Phelps [1967, 1970] and myself [1968b]) developed an alternative hypothesis that distin-guished between the short-run and long-run effects of unanticipated changes in aggregate nominal demand. Start from some initial stable position and let there be, for example, an unanticipated acceleration of aggregate nominal demand. This will come to each producer as an unexpectedly favorable demand for his product. In an environment in which changes are always occurring in the relative demand for different goods, he will not know whether this change is special to him or per-vasive. It will be rational for him to interpret it as at least partly special and to react to it by seeking to produce more to sell at what he now perceives to be a higher than expected market price for future output. He will be willing to pay higher nominal wages than he had been willing to pay before in order to attract additional workers. The real wage that

Rate of inflation

$$\left(\frac{1}{P}\frac{dP}{dt}\right)$$

Fig. 2.—Expectations-adjusted Phillips curve

matters to him is the wage in terms of the price of his product, and he perceives that price as higher than before. A higher nominal wage can therefore mean a lower *real* wage as perceived by him.

To workers, the situation is different: what matters to them is the purchasing power of wages not over the particular good they produce but over all goods in general. Both they and their employers are likely to adjust more slowly their perception of prices in general—because it is more costly to acquire information about that—than their perception of the price of the particular good they produce. As a result, a rise in nominal wages may be perceived by workers as a rise in real wages and hence call forth an increased supply at the same time that it is perceived by employers as a fall in real wages and hence calls forth an increased offer of jobs. Expressed in terms of the average of perceived future prices, real wages are lower; in terms of the perceived future average price, real wages are higher.

But this situation is temporary: let the higher rate of growth of aggregate nominal demand and of prices continue, and perceptions will adjust to reality. When they do, the initial effect will disappear and then even be reversed for a time as workers and employers find themselves locked into inappropriate contracts. Ultimately, employment will be back at the level that prevailed before the assumed unanticipated acceleration in aggregate nominal demand.

This alternative hypothesis is depicted in figure 2. Each negatively sloping curve is a Phillips curve like that in figure 1 except that it is for a particular anticipated or perceived rate of inflation, defined as the perceived average rate of price change, *not* the average of perceived rates of individual price change (the order of the curves would be reversed for the second concept). Start from point E and let the rate of inflation for whatever reason move from A to B and stay there. Unemployment would initially decline to U_L at point F, moving along the curve defined for an anticipated rate of inflation $[(1/P)(dP/dt)]^*$ of A. As anticipations

adjusted, the short-run curve would move upward, ultimately to the curve defined for an anticipated inflation rate of B. Concurrently unemployment would move gradually over from F to G. (For a fuller discussion, see Friedman [1976], chap. 12.)

This analysis is, of course, oversimplified. It supposes a single unanticipated change whereas, of course, there is a continuing stream of unanticipated changes; it does not deal explicitly with lags, or with overshooting, or with the process of formation of anticipations. But it does highlight the key points: what matters is not inflation per se but unanticipated inflation; there is no stable trade-off between inflation and unemployment; there is a "natural rate of unemployment" (U_N) which is consistent with the real forces and with accurate perceptions; unemployment can be kept below that level only by an accelerating inflation; or above it only by accelerating deflation.

The "natural rate of unemployment," a term I introduced to parallel Knut Wicksell's "natural rate of interest," is not a numerical constant but depends on "real" as opposed to monetary factors—the effectiveness of the labor market, the extent of competition or monopoly, the barriers or encouragements to working in various occupations, and so on.

For example, the natural rate has clearly been rising in the United States for two major reasons. First, women, teenagers, and part-time workers have been constituting a growing fraction of the labor force. These groups are more mobile in employment than other workers, entering and leaving the labor market, shifting more frequently between jobs. As a result, they tend to experience higher average rates of unemployment. Second, unemployment insurance and other forms of assistance to unemployed persons have been made available to more categories of workers and have become more generous in duration and amount. Workers who lose their jobs are under less pressure to look for other work, will tend to wait longer in the hope, generally fulfilled, of being recalled to their former employment, and can be more selective in the alternatives they consider. Further, the availability of unemployment insurance makes it more attractive to enter the labor force in the first place, and so may itself have stimulated both the growth that has occurred in the labor force as a percentage of the population and its changing composition.

The determinants of the natural rate of unemployment deserve much fuller analysis for both the United States and other countries. So also do the meaning of the recorded unemployment figures and the relation between the recorded figures and the natural rate. These issues are all of the utmost importance for public policy. However, they are side issues for my present limited purpose.

The connection between the state of employment and the level of efficiency or productivity of an economy is another topic that is of

fundamental importance for public policy but is a side issue for my present purpose. There is a tendency to take it for granted that a high level of recorded unemployment is evidence of inefficient use of resources, and conversely. This view is seriously in error. A low level of unemployment may be a sign of a forced-draft economy that is using its resources inefficiently and is inducing workers to sacrifice leisure for goods that they value less highly than the leisure under the mistaken belief that their real wages will be higher than they prove to be. Or a low natural rate of unemployment may reflect institutional arrangements that inhibit change. A highly static rigid economy may have a fixed place for everyone whereas a dynamic, highly progressive economy, which offers ever-changing opportunities and fosters flexibility, may have a high natural rate of unemployment. To illustrate how the same rate may correspond to very different conditions: both Japan and the United Kingdom had low average rates of unemployment from, say, 1950 to 1970, but Japan experienced rapid growth, the United Kingdom, stagnation.

The "natural-rate" or "accelerationist" or "expectations-adjusted Phillips curve" hypothesis—as it has been variously designated—is by now widely accepted by economists, though by no means universally. A few still cling to the original Phillips curve; more recognize the difference between short-run and long-run curves but regard even the long-run curve as negatively sloped, though more steeply so than the short-run curves; some substitute a stable relation between the acceleration of inflation and unemployment for a stable relation between inflation and unemployment—aware of but not concerned about the possibility that the same logic that drove them to a second derivative will drive them to ever higher derivatives.

Much current economic research is devoted to exploring various aspects of this second stage—the dynamics of the process, the formation of expectations, and the kind of systematic policy, if any, that can have a predictable effect on real magnitudes. We can expect rapid progress on these issues. (Special mention should be made of the work on "rational expectations," especially the seminal contributions of John Muth, Robert Lucas, and Thomas Sargent; see Muth [1961], Gordon [1976].)

IV. Stage 3: A Positively Sloped Phillips Curve?

Although the second stage is far from having been fully explored, let alone fully absorbed into the economic literature, the course of events is already producing a move to a third stage. In recent years higher inflation has often been accompanied by higher, not lower, unemployment, expecially for periods of several years in length. A simple statistical Phillips curve for such periods seems to be positively sloped, not vertical. The third stage is directed at accommodating this apparent empirical

phenomenon. To do so, I suspect that it will have to include in the analysis the interdependence of economic experience and political developments. It will have to treat at least some political phenomena not as independent variables—as exogenous variables in econometric jargon—but as themselves determined by economic events—as endogenous variables (Gordon 1975*b*). The second stage was greatly influenced by two major developments in economic theory of the past few decades— one, the analysis of imperfect information and of the cost of acquiring information, pioneered by George Stigler; the other, the role of human capital in determining the form of labor contracts, pioneered by Gary Becker. The third stage will, I believe, be greatly influenced by a third major development—the application of economic analysis to political behavior, a field in which pioneering work has also been done by Stigler and Becker as well as by Kenneth Arrow, Duncan Black, Anthony Downs, James Buchanan, Gordon Tullock, and others.

The apparent positive relation between inflation and unemployment has been a source of great concern to government policymakers. Let me quote from a recent speech by Prime Minister Callaghan of Great Britain: "We used to think that you could just spend your way out of a recession and increase employment by cutting taxes and boosting Government spending. I tell you, in all candour, that that option no longer exists, and that insofar as it ever did exist, it only worked by injecting bigger does of inflation into the economy followed by higher levels of unemployment as the next step. That is the history of the past 20 years" (speech to Labour Party Conference, September 28, 1976).

The same view is expressed in a Canadian government white paper: "Continuing inflation, particularly in North America, has been accompanied by an increase in measured unemployment rates" ("The Way Ahead: A Framework for Discussion," Government of Canada Working Paper, October 1976).

These are remarkable statements, running as they do directly counter to the policies adopted by almost every Western government throughout the postwar period.

A. Some Evidence

More systematic evidence for the past two decades is given in table 1 and figures 3 and 4, which show the rates of inflation and unemployment in seven industrialized countries over the past two decades. According to the 5-year averages in table 1, the rate of inflation and the level of unemployment moved in opposite directions—the expected simple Phillips curve outcome—in five out of seven countries between the first two quinquennia (1956–60, 1961–65); in only four out of seven countries between the second and third quinquennia (1961–65 and 1966–70); and

TABLE 1

INFLATION AND UNEMPLOYMENT IN SEVEN COUNTRIES, 1956–75: AVERAGE VALUES FOR SUCCESSIVE QUINQUENNIA
(DP = RATE OF PRICE CHANGE, PERCENT PER YEAR; U = UNEMPLOYMENT, PERCENTAGE OF LABOR FORCE)

YEARS	FRANCE		GERMANY		ITALY		JAPAN		SWEDEN		UNITED KINGDOM		UNITED STATES		UNWEIGHTED AVERAGE SEVEN COUNTRIES	
	DP	U	DP	U	DP	U	DP	U	DP	U	DP	U	DP	U	DP	U

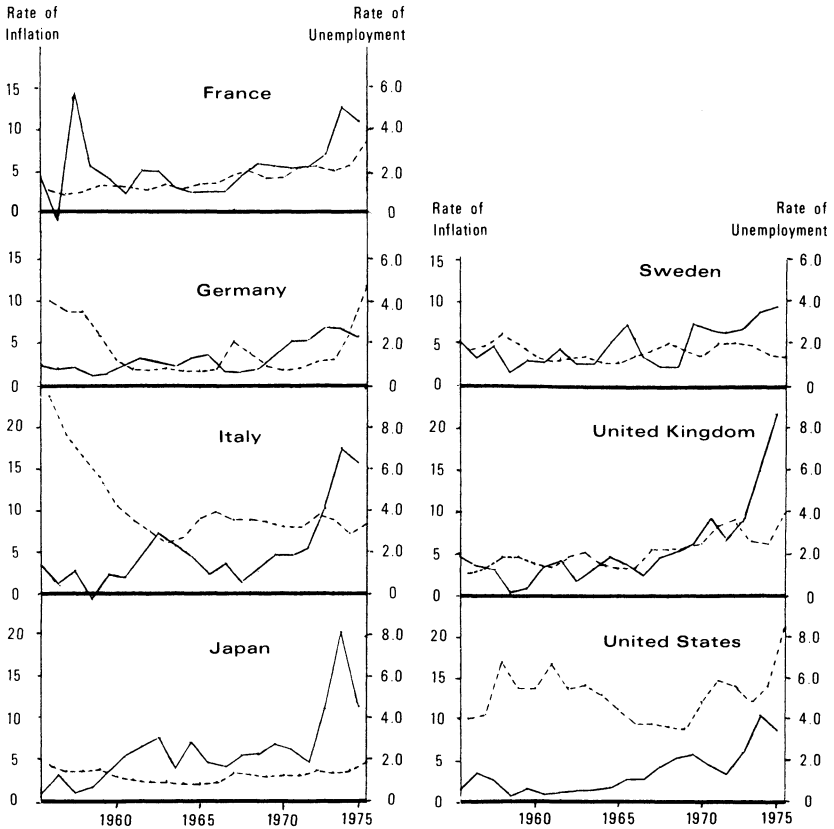

FIG. 4.—Inflation and unemployment in seven countries, annually, 1956–75. Solid line = rate of inflation; dashed line = rate of unemployment.

462

in only one out of seven countries between the final two quinquennia (1966–70 and 1970–75). And even the one exception—Italy—is not a real exception. True, unemployment averaged a shade lower from 1971 to 1975 than in the prior 5 years, despite a more than tripling of the rate of inflation. However, since 1973 both inflation and unemployment have risen sharply.

The averages for all seven countries plotted in figure 3 bring out even more clearly the shift from a negatively sloped simple Phillips curve to a positively sloped one. The two curves move in opposite directions between the first two quinquennia; in the same direction thereafter.

The annual data in figure 4 tell a similar, though more confused, story. In the early years, there is wide variation in the relation between prices and unemployment, varying from essentially no relation, as in Italy, to a fairly clear-cut year-to-year negative relation, as in the United Kingdom and the United States. In recent years, however, France, the United States, the United Kingdom, Germany, and Japan all show a clearly marked rise in both inflation and unemployment—though for Japan the rise in unemployment is much smaller relative to the rise in inflation than in the other countries, reflecting the different meaning of unemployment in the different institutional environment of Japan. Only Sweden and Italy fail to conform to the general pattern.

Of course, these data are at most suggestive. We do not really have seven independent bodies of data. Common international influences affect all countries so that multiplying the number of countries does not multiply proportionately the amount of evidence. In particular, the oil crisis hit all seven countries at the same time. Whatever effect the crisis had on the rate of inflation, it directly disrupted the productive process and tended to increase unemployment. Any such increases can hardly be attributed to the acceleration of inflation that accompanied them; at most the two could be regarded as at least partly the common result of a third influence (Gordon 1975a).

Both the quinquennial and annual data show that the oil crisis cannot wholly explain the phenomenon described so graphically by Callaghan. Already before the quadrupling of oil prices in 1973, most countries show a clearly marked association of rising inflation and rising unemployment. But this too may reflect independent forces rather than the influence of inflation on unemployment. For example, the same forces that have been raising the natural rate of unemployment in the United States may have been operating in other countries and may account for their rising trend of unemployment, independently of the consequences of inflation.

Despite these qualifications, the data strongly suggest that, at least in some countries, of which Britain, Canada, and Italy may be the best examples, rising inflation and rising unemployment have been mutually reinforcing, rather than the separate effects of separate causes. The data

are not inconsistent with the stronger statement that, in all industrialized countries, higher rates of inflation have some effects that, at least for a time, make for higher unemployment. The rest of this paper is devoted to a preliminary exploration of what some of these effects may be.

B. A Tentative Hypothesis

I conjecture that a modest elaboration of the natural-rate hypothesis is all that is required to account for a positive relation between inflation and unemployment, though of course such a positive relation may also occur for other reasons. Just as the natural-rate hypothesis explains a negatively sloped Phillips curve over short periods as a temporary phenomenon that will disappear as economic agents adjust their expectations to reality, so a positively sloped Phillips curve over somewhat longer periods may occur as a transitional phenomenon that will disappear as economic agents adjust not only their expectations but their institutional and political arrangements to a new reality. When this is achieved, I believe that—as the natural-rate hypothesis suggests—the rate of unemployment will be largely independent of the average rate of inflation, though the efficiency of utilization of resources may not be. High inflation need not mean either abnormally high or abnormally low unemployment. However, the institutional and political arrangements that accompany it, either as relics of earlier history or as products of the inflation itself, are likely to prove antithetical to the most productive use of employed resources—a special case of the distinction between the state of employment and the productivity of an economy referred to earlier.

Experience in many Latin American countries that have adjusted to chronically high inflation rates—experience that has been analyzed most perceptively by some of my colleagues, particularly Arnold Harberger (1967) and Larry Sjaastad (1974)—is consistent, I believe, with this view.

In the version of the natural-rate hypothesis summarized in figure 2, the vertical curve is for alternative rates of fully anticipated inflation. Whatever that rate—be it negative, zero or positive—it can be built into every decision if it is fully anticipated. At an anticipated 20 percent per year inflation, for example, long-term wage contracts would provide for a wage in each year that would rise relative to the zero-inflation wage by just 20 percent per year; long-term loans would bear an interest rate 20 percent higher than the zero-inflation rate or a principal that would be raised by 20 percent a year; and so on—in short, the equivalent of a full indexing of all contracts. The high rate of inflation would have some real effects, by altering desired cash balances, for example, but it need not alter the efficiency of labor markets, or the length or terms of labor contracts, and hence it need not change the natural rate of unemployment.

This analysis implicitly supposes, first, that inflation is steady or at

least no more variable at a high rate than at a low—otherwise, it is unlikely that inflation would be as fully anticipated at high as at low rates of inflation; second, that the inflation is, or can be, open, with all prices free to adjust to the higher rate, so that relative price adjustments are the same with a 20 percent inflation as with a zero inflation; third, really a variant of the second point, that there are no obstacles to indexing of contracts.

Ultimately, if inflation at an average rate of 20 percent per year were to prevail for many decades, these requirements could come fairly close to being met, which is why I am inclined to retain the long-long-run vertical Phillips curve. But when a country initially moves to higher rates of inflation, these requirements will be systematically departed from. And such a transitional period may well extend over decades.

Consider, in particular, the United States and the United Kingdom. For 2 centuries before World War II for the United Kingdom, and a century and a half for the United States, prices varied about a roughly constant level, showing substantial increases in time of war, then postwar declines to roughly prewar levels. The concept of a "normal" price level was deeply imbedded in the financial and other institutions of the two countries and in the habits and attitudes of their citizens.

In the immediate post–World War II period, prior experience was widely expected to recur. The fact was postwar inflation superimposed on wartime inflation; yet the expectation in both countries was deflation. It took a long time for the fear of postwar deflation to dissipate—if it still has—and still longer before expectations started to adjust to the fundamental change in the monetary system. That adjustment is still far from complete (Klein 1975).

Indeed, we do not know what a complete adjustment will consist of. We cannot know now whether the industrialized countries will return to the pre–World War II pattern of a long-term stable price level, or will move toward the Latin American pattern of chronically high inflation rates—with every now and then an acute outbreak of super- or hyper-inflation, as occurred recently in Chile and Argentina (Harberger 1976)—or will undergo more radical economic and political change leading to a still different resolution of the present ambiguous situation.

This uncertainty—or more precisely, the circumstances producing this uncertainty—leads to systematic departures from the conditions required for a vertical Phillips curve.

The most fundamental departure is that a high inflation rate is not likely to be steady during the transition decades. Rather, the higher the rate, the more variable it is likely to be. That has been empirically true of differences among countries in the past several decades (Jaffe and Kleiman 1975; Logue and Willett 1976). It is also highly plausible on theoretical grounds—both about actual inflation and, even more clearly,

the anticipations of economic agents with respect to inflation. Govern-
ments have not produced high inflation as a deliberate announced policy
but as a consequence of other policies—in particular, policies of full
employment and welfare-state policies raising government spending.
They all proclaim their adherence to the goal of stable prices. They do so
in response to their constituents, who may welcome many of the side
effects of inflation but are still wedded to the concept of stable money. A
burst of inflation produces strong pressure to counter it. Policy goes from
one direction to the other, encouraging wide variation in the actual and
anticipated rate of inflation. And, of course, in such an environment, no
one has single-valued anticipations. Everyone recognizes that there is
great uncertainty about what actual inflation will turn out to be over any
specific future interval (Jaffe and Kleiman 1975; Meiselman 1976).

The tendency for inflation that is high on the average to be highly
variable is reinforced by the effect of inflation on the political cohesiveness
of a country in which institutional arrangements and financial contracts
have been adjusted to a long-term "normal" price level. Some groups
gain (e.g., homeowners); others lose (e.g., owners of savings accounts and
fixed-interest securities). "Prudent" behavior becomes in fact reckless,
and "reckless" behavior in fact prudent. The society is polarized; one
group is set against another. Political unrest increases. The capacity of
any government to govern is reduced at the same time that the pressure
for strong action grows.

An increased variability of actual or anticipated inflation may raise
the natural rate of unemployment in two rather different ways.

First, increased volatility shortens the optimum length of unindexed
commitments and renders indexing more advantageous (Gray 1976).
But it takes time for actual practice to adjust. In the meantime, prior
arrangements introduce rigidities that reduce the effectiveness of markets.
An additional element of uncertainty is, as it were, added to every market
arrangement. In addition, indexing is, even at best, an imperfect sub-
stitute for stability of the inflation rate. Price indexes are imperfect; they
are available only with a lag and generally are applied to contract terms
only with a further lag.

These developments clearly lower economic efficiency. It is less clear
what their effect is on recorded unemployment. High average inventories
of all kinds are one way to meet increased rigidity and uncertainty. But
that may mean labor hoarding by enterprises and low unemployment or
a larger force of workers between jobs and so high unemployment.
Shorter commitments may mean more rapid adjustment of employment
to changed conditions and so low unemployment, or the delay in ad-
justing the length of commitments may lead to less satisfactory adjustment
and so high unemployment. Clearly, much additional research is necessary
in this area to clarify the relative importance of the various effects. About
all one can say now is that the slow adjustment of commitments and the

imperfections of indexing may contribute to the recorded increase in unemployment.

A second related effect of increased volatility of inflation is to render market prices a less efficient system for coordinating economic activity. A fundamental function of a price system, as Hayek (1945) emphasized so brilliantly, is to transmit compactly, efficiently, and at low cost the information that economic agents need in order to decide what to produce and how to produce it, or how to employ owned resources. The relevant information is about *relative* prices—of one product relative to another, of the services of one factor of production relative to another, of products relative to factor services, of prices now relative to prices in the future. But the information in practice is transmitted in the form of *absolute* prices—prices in dollars or pounds or kronor. If the price level is on the average stable or changing at a steady rate, it is relatively easy to extract the signal about relative prices from the observed absolute prices. The more volatile the rate of general inflation, the harder it becomes to extract the signal about relative prices from the absolute prices: the broadcast about relative prices is, as it were, being jammed by the noise coming from the inflation broadcast (Lucas 1973, 1975; Harberger 1976). At the extreme, the system of absolute prices becomes nearly useless, and economic agents resort either to an alternative currency or to barter, with disastrous effects on productivity.

Again, the effect on economic efficiency is clear, on unemployment less so. But, again, it seems plausible that the average level of unemployment would be raised by the increased amount of noise in market signals, at least during the period when institutional arrangements are not yet adapted to the new situation.

These effects of increased volatility of inflation would occur even if prices were legally free to adjust—if, in that sense, the inflation were open. In practice, the distorting effects of uncertainty, rigidity of voluntary long-term contracts, and the contamination of price signals will almost certainly be reinforced by legal restrictions on price change. In the modern world, governments are themselves producers of services sold on the market: from postal services to a wide range of other items. Other prices are regulated by government and require government approval for change: from air fares to taxicab fares to charges for electricity. In these cases, governments cannot avoid being involved in the price-fixing process. In addition, the social and political forces unleashed by volatile inflation rates will lead governments to try to repress inflation in still other areas: by explicit price and wage control, or by pressuring private businesses or unions "voluntarily" to exercise "restraint," or by speculating in foreign exchange in order to alter the exchange rate.

The details will vary from time to time and from country to country, but the general result is the same: reduction in the capacity of the price system to guide economic activity; distortions in relative prices because

of the introduction of greater friction, as it were, in all markets; and, very likely, a higher recorded rate of unemployment (Friedman 1976, chap. 12).

The forces I have just described may render the political and economic system dynamically unstable and produce hyperinflation and radical political change—as in many defeated countries after World War I, or in Chile and Argentina more recently. At the other extreme, before any such catastrophe occurs, policies may be adopted that will achieve a relatively low and stable rate of inflation and lead to the dismantling of many of the interferences with the price system. That would reestablish the preconditions for the straight-forward natural-rate hypothesis and enable that hypothesis to be used to predict the course of the transition.

An intermediate possibility is that the system will reach stability at a fairly constant though high average rate of inflation. In that case, unemployment should also settle down to a fairly constant level decidedly lower than during the transition. As the preceding discussion emphasizes, *increasing* volatility and *increasing* government intervention with the price system are the major factors that seem likely to raise unemployment, not *high* volatility or a *high* level of intervention.

Ways of coping with both volatility and intervention will develop: through indexing and similar arrangements for coping with volatility of inflation; through the development of indirect ways of altering prices and wages for avoiding government controls.

Under these circumstances, the long-run Phillips curve would again be vertical and we would be back at the natural-rate hypothesis, though perhaps for a different range of inflation rates than that for which it was first suggested.

Because the phenomenon to be explained is the coexistence of high inflation and high unemployment, I have stressed the effect of institutional changes produced by a transition from a monetary system in which there was a "normal" price level to a monetary system consistent with long periods of high, and possibly highly variable, inflation. It should be noted that once these institutional changes were made, and economic agents had adjusted their practices and anticipations to them, a reversal to the earlier monetary framework or even the adoption in the new monetary framework of a successful policy of low inflation would in its turn require new adjustments, and these might have many of the same adverse transitional effects on the level of employment. There would appear to be an intermediate-run negatively sloped Phillips curve instead of the positively sloped one I have tried to rationalize.

V. Conclusion

One consequence of the Keynesian revolution of the 1930s was the acceptance of a rigid absolute wage level, and a nearly rigid absolute price level, as a starting point for analyzing short-term economic change.

It came to be taken for granted that these were essentially institutional data and were so regarded by economic agents, so that changes in aggregate nominal demand would be reflected almost entirely in output and hardly at all in prices. The age-old confusion between absolute prices and relative prices gained a new lease on life.

In this intellectual atmosphere it was understandable that economists would analyze the relation between unemployment and *nominal* rather than *real* wages and would implicitly regard changes in anticipated *nominal* wages as equal to changes in anticipated *real* wages. Moreover, the empirical evidence that initially suggested a stable relation between the level of unemployment and the rate of change of nominal wages was drawn from a period when, despite sharp short-period fluctuations in prices, there was a relatively stable long-run price level and when the expectation of continued stability was widely shared. Hence these data flashed no warning signals about the special character of the assumptions.

The hypothesis that there is a stable relation between the level of unemployment and the rate of inflation was adopted by the economics profession with alacrity. It filled a gap in Keynes's theoretical structure. It seemed to be the "one equation" that Keynes himself had said "we are . . . short" (1936, p. 276). In addition, it seemed to provide a reliable tool for economic policy, enabling the economist to inform the policy-maker about the alternatives available to him.

As in any science, so long as experience seemed to be consistent with the reigning hypothesis it continued to be accepted, although, as always, a few dissenters questioned its validity.

But as the '50s turned into the '60s, and the '60s into the '70s, it became increasingly difficult to accept the hypothesis in its simple form. It seemed to take larger and larger doses of inflation to keep down the level of unemployment. Stagflation reared its ugly head.

Many attempts were made to patch up the hypothesis by allowing for special factors such as the strength of trade unions. But experience stubbornly refused to conform to the patched-up versions.

A more radical revision was required. It took the form of stressing the importance of surprises—of differences between actual and anticipated magnitudes. It restored the primacy of the distinction between real and nominal magnitudes. There is a natural rate of unemployment at any time determined by real factors. This natural rate will tend to be attained when expectations are on the average realized. The same real situation is consistent with any absolute level of prices or of price change, provided allowance is made for the effect of price change on the real cost of holding money balances. In this respect, money is neutral. On the other hand, unanticipated changes in aggregate nominal demand and in inflation will cause systematic errors of perception on the part of employers and employees alike that will initially lead unemployment to deviate in the opposite direction from its natural rate. In this respect, money is not

neutral. However, such deviations are transitory, though it may take a long chronological time before they are reversed and finally eliminated as anticipations adjust.

The natural-rate hypothesis contains the original Phillips curve hypothesis as a special case and rationalizes a far broader range of experience, in particular the phenomenon of stagflation. It has by now been widely though not universally accepted.

However, the natural-rate hypothesis in its present form has not proved rich enough to explain a more recent development—a move from stagflation to slumpflation. In recent years, higher inflation has often been accompanied by higher unemployment—not lower unemployment, as the simple Phillips curve would suggest, nor the same unemployment, as the natural-rate hypothesis would suggest.

This recent association of higher inflation with higher unemployment may reflect the common impact of such events as the oil crisis, or independent forces that have imparted a common upward trend to inflation and unemployment.

However, a major factor in some countries and a contributing factor in others may be that they are in a transitional period—this time to be measured by quinquennia or decades not years. The public has not adapted its attitudes or its institutions to a new monetary environment. Inflation tends not only to be higher but also increasingly volatile and to be accompanied by widening government intervention into the setting of prices. The growing volatility of inflation and the growing departure of relative prices from the values that market forces alone would set combine to render the economic system less efficient, to introduce frictions in all markets, and, very likely, to raise the recorded rate of unemployment.

On this analysis, the present situation cannot last. It will either degenerate into hyperinflation and radical change, or institutions will adjust to a situation of chronic inflation, or governments will adopt policies that will produce a low rate of inflation and less government intervention into the fixing of prices.

I have told a perfectly standard story of how scientific theories are revised. Yet it is a story that has far-reaching importance.

Government policy about inflation and unemployment has been at the center of political controversy. Ideological war has raged over these matters. Yet the drastic change that has occurred in economic theory has not been a result of ideological warfare. It has not resulted from divergent political beliefs or aims. It has responded almost entirely to the force of events: brute experience proved far more potent than the strongest of political or ideological preferences.

The importance for humanity of a correct understanding of positive economic science is vividly brought out by a statement made nearly two

hundred years ago by Pierre S. du Pont, a deputy from Nemours to the French National Assembly, speaking, appropriately enough, on a proposal to issue additional assignats—the fiat money of the French Revolution: "Gentlemen, it is a disagreeable custom to which one is too easily led by the harshness of the discussions, to assume evil intentions. It is necessary to be gracious as to intentions; one should believe them good, and apparently they are; but we do not have to be gracious at all to inconsistent logic or to absurd reasoning. Bad logicians have committed more involuntary crimes than bad men have done intentionally" (September 25, 1790).
